

THE STABILITY OF DECELERATING SHOCKS REVISITED

DORON KUSHNIR¹, ELI WAXMAN² AND DOV SHVARTS^{1,3}

Draft version February 2, 2008

ABSTRACT

We present a new method for analyzing the global stability of the Sedov-von Neumann-Taylor self-similar solutions, describing the asymptotic behavior of spherical decelerating shock waves, expanding into ideal gas with density $\propto r^{-\omega}$. Our method allows to overcome the difficulties associated with the non-physical divergences of the solutions at the origin. We show that while the growth rates of global modes derived by previous analyses are accurate in the large wave number (small wavelength) limit, they do not correctly describe the small wave number behavior for small values of the adiabatic index γ . Our method furthermore allows to analyze the stability properties of the flow at early times, when the flow deviates significantly from the asymptotic self-similar behavior. We find that at this stage the perturbation growth rates are larger than those obtained for unstable asymptotic solutions at similar $[\gamma, \omega]$. Our results reduce the discrepancy that exists between theoretical predictions and experimental results.

Subject headings: hydrodynamics — instabilities — shock waves

1. INTRODUCTION

Shock waves play a crucial role in the evolution of a wide variety of astrophysical systems, such as the interstellar medium and the inter-galactic medium (for review see, e.g., Ostriker & McKee 1988). The study of shock wave properties, and in particular of shock wave stability, is therefore relevant for a wide variety of astrophysical phenomena. The stability of planar steady shocks propagating into a uniform medium was demonstrated by Erpenbeck (1962). The stability of 1D shocks (with planar/cylindrical/spherical symmetry) propagating into both uniform and non-uniform media is commonly studied by analyzing self-similar shock solutions of the hydrodynamic equations, since self-similar solutions often allow analytic stability analysis and since in many cases self-similar solutions describe the asymptotic behavior of the flow (see, e.g., Zeldovich & Raizer 1968).

Ryu & Vishniac (1987,1991) have studied the stability of the self-similar Sedov-von Neumann-Taylor solutions (Sedov 1946; Von Neumann 1947; Taylor 1950), describing spherical shocks propagating into an ideal gas with a power-law density profile $\rho \propto r^{-\omega}$. They have studied both the "local" and the "global" stability of the solutions. The term "local" stability analysis refers to approximate analysis of stability where flow properties are considered in a small region, where the spatial dependence of flow variables may be approximated as linear, and boundary conditions are neglected. The term "global" stability refers to stability against perturbations with time independent spatial structure, which satisfy the flow boundary conditions. Analysis of stability against global modes of perturbation is often not useful for general time dependent flows, with time dependent spatial structure. Self-similar flows are an ex-

ception, since the spatial structure of such flows is time independent.

The amplitude of global modes of perturbations to the Sedov-von Neumann-Taylor solutions evolves with time as t^s . For expansion into uniform media ($\omega = 0$), the Sedov-von Neumann-Taylor shocks were found to be stable ($Re(s) < 0$) for gas adiabatic index $\gamma > 1.2$, and unstable (for a limited range of perturbation wave numbers) for $\gamma < 1.2$, where the high density region behind the shock is sufficiently thin. Qualitatively similar results are obtained from the analysis of Ryu & Vishniac for ω values in the range $0 < \omega < (7 - \gamma)/(\gamma + 1)$. For larger values of ω , $(7 - \gamma)/(\gamma + 1) < \omega < 3$, the solutions are "hollow," i.e., the density vanishes at some finite distance (behind the shock) away from the origin. The stability of "hollow" solutions was examined by Goodman (1990), who found that the flow is unstable for large perturbation wave numbers l , with growth rate scaling as $l^{1/2}$. The local stability analysis of Ryu & Vishniac (1991) showed that the flow in the non-hollow solutions is convectively unstable (to local perturbations) in the range $3/\gamma < \omega < (7 - \gamma)/(\gamma + 1)$. The growth rate of the perturbation was studied numerically in one specific case ($\omega = 0, \gamma = 1.1, l = 40$) by Mac Low & Norman (1993), and was found to be in good agreement with the prediction of Ryu & Vishniac.

Shock waves propagating into a steep density gradient $\omega > 3$, are accelerating. The asymptotic behavior of such shocks is not described by the Sedov-von Neumann-Taylor solutions, but rather by a different family of self-similar solutions, derived by Waxman & Shvarts (1993). The stability of these solutions against global modes of perturbations was examined by Sari, Waxman & Shvarts (2000), who found that shock waves that accelerate at a rate faster than the critical rate $\ddot{R}R/\dot{R}^2 = 1$ are unstable for small and intermediate wave numbers, whereas shock waves accelerating at a slower rate, $\ddot{R}R/\dot{R}^2 < 1$, are stable for most wave numbers (here, $R(t)$ denotes the time dependent shock radius). They have further shown that perturbations of small wave numbers grow or decay monotonically, while

perturbations of intermediate and high wave numbers oscillate in time.

The stability of spherical shocks propagating into a uniform medium was studied experimentally by Grun et al. (1991). For shocks propagating in Xenon, with adiabatic index $\gamma = 1.06 \pm 0.02$, perturbations growing as a power law of time were found, while in Nitrogen, $\gamma = 1.3 \pm 0.1$, shocks were found to be stable. These results are in qualitative agreement with the predictions of Ryu & Vishniac (1987). However, the maximum growth rate measured was higher than the Ryu & Vishniac prediction by a factor of ~ 1.7 , and was obtained at lower than predicted wave numbers, $l \sim 10$ instead of $l \sim 60$.

The cause for the discrepancy between the experimental results and the theoretical predictions is yet unknown. On the one hand, there are some preliminary claims that the experimental results of Grun et al. (1991) are not accurate (Hansen et al. 2002). On the other hand, there are some difficulties in the theoretical analysis. Briefly, the Sedov-von Neumann-Taylor solutions for $\omega < (7 - \gamma)/(\gamma + 1)$ show non-physical divergences near the origin, reflecting the fact that for any physical initial conditions the flow deviates significantly from the asymptotic self-similar solution at all times for sufficiently small radii, and the analysis of Ryu & Vishniac (1987, 1991) relies on applying boundary conditions for the perturbation equations at the origin. This leads, for example, to non physical results of the stability analysis for small wave number (large wave length) perturbations (see § 4).

In this paper we present a new method, free of such difficulties, for determining shock stability against global perturbations. We analyze the stability of solutions which coincide with the Sedov-Taylor-von Neumann solutions everywhere except for some region of finite mass, m , near the origin. We show that the global stability of the flow is independent of the details of the solution in the region where it deviates from self-similarity, and obtain the stability properties of the self-similar solution by taking the limit $m \rightarrow 0$. We find that while the growth rates derived by the method of Ryu & Vishniac approach our growth rates for large wave number (small wavelength) perturbations, they do not correctly describe the small wave number behavior for small values of the adiabatic index γ . We furthermore argue that the growth rates obtained for finite values of m describe the stability properties of the flow at early times, when the flow deviates significantly from the asymptotic self-similar behavior. We find that at this stage the perturbation growth rates are larger than those obtained for unstable asymptotic solutions at similar $[\gamma, \omega]$.

Several attempts to resolve the discrepancy between theoretical and experimental results have been made recently, based on atomic-physics calculations of radiative cooling which suggest that the effective adiabatic index of the gas relevant for the experiment is lower than previously estimated (Laming & Grun 2002, 2003). These recent analyses predict larger growth rates, reducing the discrepancy with the experimental growth rates. However, the most unstable modes are predicted to have larger wave numbers, $l \sim 200$, increasing the discrepancy with the experimental results, $l \sim 10$. In our analysis, the large growth rates obtained in the experiment may

be explained as due to instabilities of the flow at a stage where it significantly deviates from self-similarity (finite m). The most unstable modes predicted by our linear analysis are still characterized by larger wave numbers ($l \sim 50$) than obtained by Grun et al. (1991). However, since the growth rates predicted by our analysis for large wave numbers, $l \sim 50$, in the pre-asymptotic stage are large, we expect the evolution of perturbations to become non-linear at an early stage. The non-linear interaction at large wave numbers may lead to perturbation amplitudes at smaller wave numbers, $l \sim 10$, which are larger than predicted by linear analysis.

This article is organized as follows. In § 2 we provide a brief description of the (unperturbed) self-similar shock solutions, with particular emphasis on flow properties near the origin. The perturbation analysis method is described in § 3. The method that allows to overcome the difficulties posed by the divergences near the origin is described in § 3.2. The stability analysis results are described in § 4. A discussion of our results and of their implications to the experimental results is given in § 5.

2. THE UNPERTURBED SHOCK SOLUTIONS

Consider the strong explosion problem, where a large amount of energy is released at the center of a sphere of ideal gas with a density profile decreasing with distance from the origin as $\rho = Kr^{-\omega}$. The energy release drives a strong outgoing shock wave. We present below a brief description of the derivation of the Sedov-von Neumann-Taylor solutions, that describe the asymptotic behavior of the flow (approached as the shock radius diverges) for $\omega < 3$, and point out some of their properties that are relevant for our perturbation analysis.

2.1. The self-similar solutions

The hydrodynamic equations describing the flow of an ideal gas with adiabatic index γ in a spherically symmetric geometry are:

$$\begin{aligned} (\partial_t + u\partial_r)\rho + \rho r^{-2}\partial_r(r^2u) &= 0, \\ \rho(\partial_t + u\partial_r)u + \partial_r(\gamma^{-1}\rho c^2) &= 0, \\ (\partial_t + u\partial_r)(\gamma^{-1}c^2\rho^{1-\gamma}) &= 0, \end{aligned} \quad (1)$$

where the dependent variables u , c , and ρ are the fluid velocity, sound velocity, and density respectively. The pressure is given via equation of state for ideal gas as: $p = \rho c^2/\gamma$. A self-similar solution to the hydrodynamic equations (1) is a solution of the form :

$$\begin{aligned} u(r, t) &= \dot{R}\xi U(\xi), & c(r, t) &= \dot{R}\xi C(\xi), \\ \rho(r, t) &= BR^\epsilon G(\xi), & p(r, t) &= BR^\epsilon \dot{R}^2 P(\xi), \end{aligned} \quad (2)$$

where $\xi = r/R(t)$ is the dimensionless spatial coordinate and the length scale $R(t)$, which is chosen in the present case to be the shock radius, satisfies (Zeldovich & Raizer 1968; Waxman & Shvarts 1993) :

$$\frac{\ddot{R}R}{\dot{R}^2} = \delta \Rightarrow \dot{R} \propto R^\delta. \quad (3)$$

The quantities G , C , U , and P defined by these equations give the spatial dependence of the hydrodynamic quantities. The diverging (exploding) solutions of equation (3) are :

$$R(t) = \begin{cases} A(t - t_0)^\alpha, & \delta < 1, \\ Ae^{t/\tau}, & \delta = 1, \\ A(t_0 - t)^\alpha, & \delta > 1, \end{cases} \quad (4)$$

where $\alpha = 1/(1 - \delta)$.

The similarity parameter ϵ is determined by the boundary conditions. These are determined at the shock, $\xi = 1$, by the Rankine-Hugoniot relations (Landau & Lifshitz 1987). These relations applied to the self-similar solution imply $\epsilon = -\omega$ and

$$\begin{aligned} U(1) &= \frac{2}{\gamma + 1}, \\ C(1) &= \frac{\sqrt{2\gamma(\gamma - 1)}}{\gamma + 1}, \\ G(1) &= \frac{\gamma + 1}{\gamma - 1}. \end{aligned} \quad (5)$$

Substituting equation (2) into the hydrodynamic equations (1) and using equation (3), the set of partial differential equations is reduced to a single ordinary differential equation (Zeldovich & Raizer 1968; Meyer-ter-Vehn 1982)

$$\frac{dU}{dC} = \frac{\Delta_1(U, C)}{\Delta_2(U, C)}, \quad (6)$$

and one quadrature

$$\frac{d \log \xi}{dU} = \frac{\Delta(U, C)}{\Delta_1(U, C)} \quad \text{or} \quad \frac{d \log \xi}{dC} = \frac{\Delta(U, C)}{\Delta_2(U, C)}. \quad (7)$$

The functions Δ, Δ_1 , and Δ_2 are

$$\begin{aligned} \Delta &= C^2 - (1 - U)^2, \\ \Delta_1 &= U(1 - U)(1 - U - \frac{\alpha - 1}{\alpha}) \\ &\quad - C^2(3U - \frac{\omega - 2[(\alpha - 1)/\alpha]}{\gamma}), \\ \Delta_2 &= C[(1 - U)(1 - U - \frac{\alpha - 1}{\alpha}) \\ &\quad - \frac{\gamma - 1}{2}U(2(1 - U) + \frac{\alpha - 1}{\alpha}) - C^2 \\ &\quad + \frac{(\gamma - 1)\omega + 2[(\alpha - 1)/\alpha]}{2\gamma} \frac{C^2}{1 - U}], \end{aligned} \quad (8)$$

and G is given implicitly by

$$C^{-2}(1 - U)^\lambda G^{\gamma - 1 + \lambda} \xi^{3\lambda - 2} = \text{const.}, \quad (9)$$

with

$$\lambda = \frac{\gamma\omega - 3}{3 - \omega}. \quad (10)$$

The value of δ is determined by the conservation of energy. Requiring the total energy to be time independent gives $\delta = (\omega - 3)/2$ (for $\omega > 3$ the energy in the Sedov-von Neumann-Taylor solutions diverges, and δ is determined by a different argument, see Waxman & Shvarts 1993).

2.2. The behavior near the origin for $\omega < \omega_{\text{hollow}}$

The flow properties are qualitatively different in the two regimes $\omega < (7 - \gamma)/(\gamma + 1) \equiv \omega_{\text{hollow}}$ and $\omega_{\text{hollow}} < \omega < 3$. For $\omega < \omega_{\text{hollow}}$ U tends to $1/\gamma$ and C tends to infinity as ξ tends to zero. For $\omega > \omega_{\text{hollow}}$, the self-similar solution becomes "hollow." There exists some finite $\xi_{\text{in}} > 0$ such that the spatial region $\xi < \xi_{\text{in}}$ is evacuated ($\rho = 0$). The self-similar solution describes the flow for $\xi_{\text{in}} \leq \xi \leq 1$ and is connected to the evacuated region $\xi < \xi_{\text{in}}$ by a weak or tangential discontinuity, which lies

at $\xi = \xi_{\text{in}}$. In this case, U tends to 1 and C tends to 0 as ξ tends to ξ_{in} .

Let us examine in more detail the $\omega < \omega_{\text{hollow}}$ solutions. It is straight forward to show that in the limit $\xi \rightarrow 0$ we have, to leading orders in ξ ,

$$\begin{aligned} U(\xi) &= 1/\gamma + U_1 \xi^a, \\ C(\xi) &= C_0 \xi^{-a/2} + C_1 \xi^{a/2}, \\ G(\xi) &= G_0 \xi^{a-2} + G_1 \xi^{2a-2}, \\ P(\xi) &= P_0 + P_1 \xi^a, \end{aligned} \quad (11)$$

where

$$a = \frac{1 + \gamma(2 - \omega)}{\gamma - 1}. \quad (12)$$

Note that $a > 2$ for $\omega < 3/\gamma$ (and $\gamma > 1$). Hence, the entropy (and temperature) diverge as ξ tends to zero. This divergence is due to the fact that in the self-similar solution the shock becomes infinitely strong (infinite Mach number) as $R \rightarrow 0$, which implies that the entropy of the gas shocked at $R \rightarrow 0$ tends to infinity. For any physical flow, where the energy is released within a finite radius, the entropy approaches a finite value as $r \rightarrow 0$. This is the origin of the difficulties in choosing proper boundary conditions for the stability analysis (see § 3.2). For the case $3/\gamma < \omega < \omega_{\text{hollow}}$ the flow is convectively unstable, as indicated by Ryu & Vishniac (1991).

3. PERTURBATION ANALYSIS

We first derive the equations describing global perturbation evolution in § 3.1, and then discuss the proper boundary conditions in § 3.2.

3.1. Perturbation equations

We use here the Eulerian perturbation approach, i.e. we define the perturbed quantities as the difference between the perturbed solution and the unperturbed one in the same spatial point. The derivation of the perturbation equation is similar to the one given in Ryu & Vishniac (1987, 1991). We therefore give here only the definitions and the main results. We define

$$\begin{aligned} \delta \mathbf{u}(r, \theta, \varphi, t) &= \mathbf{u}(r, \theta, \varphi, t) - u_0(r, t) \hat{\mathbf{r}}, \\ \delta \rho(r, \theta, \varphi, t) &= \rho(r, \theta, \varphi, t) - \rho_0(r, t), \\ \delta p(r, \theta, \varphi, t) &= p(r, \theta, \varphi, t) - p_0(r, t), \end{aligned} \quad (13)$$

where $\mathbf{u}$, p , and ρ are the velocity, pressure and density in the perturbed solution and $u_0 \hat{\mathbf{r}}$, p_0 , and ρ_0 are the same quantities in the unperturbed solution. In this analysis, as in Ryu & Vishniac (1987, 1991), Chevalier (1990), Goodman (1990), and Sari, Waxman & Shvarts (2000), only "global" perturbations are considered, i.e. perturbations that can be written in a separation-of-variables form (Cox 1980) :

$$\begin{aligned} \delta \mathbf{u}(r, \theta, \varphi, t) &= \xi \dot{R} [\delta U_r(\xi) Y_{l,m}(\theta, \varphi) \hat{\mathbf{r}} - \delta U_T(\xi) \nabla_{\mathbf{T}} Y_{l,m}(\theta, \varphi)] f(t), \\ \delta \rho(r, \theta, \varphi, t) &= BR^\epsilon \delta G(\xi) Y_{l,m}(\theta, \varphi) f(t), \\ \delta p(r, \theta, \varphi, t) &= BR^\epsilon \dot{R}^2 \delta P(\xi) Y_{l,m}(\theta, \varphi) f(t), \end{aligned} \quad (14)$$

where

$$\nabla_{\mathbf{T}} = \hat{\theta} \frac{\partial}{\partial \theta} + \hat{\varphi} \frac{1}{\sin \theta} \frac{\partial}{\partial \varphi} \quad (15)$$

is the tangential component of the gradient. $R(t)$ or simply R is the unperturbed shock radius. The perturbed

shock radius, $R(t, \theta, \varphi)$, is given by

$$R(t, \theta, \varphi) - R(t) \equiv \delta R(t, \theta, \varphi) = R(t) Y_{l,m}(\theta, \varphi) f(t), \quad (16)$$

and the dimensionless spatial coordinate, ξ , is normalized with respect to the perturbed shock radius, $\xi \equiv r/(R + \delta R)$.

Equations (14) and (16) are the definitions of the quantities δU_r , δU_T , δP , δG , and f . The quantity f measure the amplitude of the perturbation relative to the unperturbed values. If the function f is bounded for any time then the solution is stable, while if f is unbounded then the solution is unstable. The question of stability is therefore a question of solving for the function f .

Linearizing the hydrodynamic equations around the unperturbed self-similar solution one obtains (Ryu & Vishniac 1987; Chevalier 1990):

$$\begin{aligned} & \delta G (q - \omega + 3U + \xi U') + \xi \delta G' (U - 1) + \delta U_r (\xi G' + 3G) \\ & + G \xi \delta U_r' - l(l+1) \xi G \delta U_T = 0, \\ & (\delta + q + 2U - 1 + \xi U') G \xi \delta U_r + (U - 1) G \xi^2 \delta U_r' \\ & + \delta P' - P' \frac{\delta G}{G} = 0, \\ & (\delta + q + 2U - 1) G \xi \delta U_T + (U - 1) G \xi^2 \delta U_T' + \xi^{-1} \delta P = 0, \\ & q \frac{\delta P}{P} - \gamma q \frac{\delta G}{G} + (U - 1) \left[\frac{\xi}{P} \delta P - \gamma \frac{\xi}{G} \delta G' - \frac{\xi P'}{P^2} \delta P \right. \\ & \left. + \gamma \frac{\xi G'}{G^2} \delta G \right] + \left(\frac{P'}{P} - \gamma \frac{G'}{G} \right) \xi \delta U_r = 0, \end{aligned} \quad (17)$$

where

$$\frac{\dot{f} R}{f \dot{R}} \equiv q = \text{const.}, \quad (18)$$

allows for variable separation.

The value of q , defined in equation (18), is in general a complex number. The perturbation amplitudes are, in general, also complex, and the physical solution is obtained by taking the real part of the complex solution. The time dependence of the perturbation amplitude, $f \propto R^q \propto t^{\alpha q}$, can be written as

$$f \propto t^{\text{Re}(s)} \exp[i \text{Im}(s) \ln t] \quad \text{with} \quad s \equiv \alpha q. \quad (19)$$

Thus, the real part of s describes a power law growth (or decay) of the perturbation amplitude, and the imaginary part describes oscillations of the perturbation amplitude with $\log(\text{time})$. Positive (negative) values of $\text{Re}(q)$ correspond to unstable (stable) perturbations.

3.2. Boundary conditions

The value of the parameter q is determined by the boundary conditions. At the shock front, the linearized Rankine-Hugoniot jump conditions are expressed as

$$\begin{aligned} \delta G(1) &= -\frac{\gamma+1}{\gamma-1} \omega - G', \\ \delta U_r(1) &= \frac{2}{\gamma+1} q - U', \\ \delta U_T(1) &= \frac{2}{\gamma+1}, \\ \delta P(1) &= \frac{2}{\gamma+1} [2(q+1) - \omega] - P'. \end{aligned} \quad (20)$$

For the case of $3 > \omega > \omega_{\text{hollow}}$, where the unperturbed solution is evacuated within $\xi < \xi_{in}$, the proper (physical) boundary condition at an interface between fluid and vacuum is that the Lagrangian pressure perturbation vanish (Goodman 1990). For the case of $\omega < \omega_{\text{hollow}}$, Ryu & Vishniac (1987, 1991) required $\delta P(0) = 0$ in order for the fluid not to undergo divergent perturbations in the Lagrangian sense at the origin. However, as explained in § 2.2, the unperturbed solution shows non physical divergences at the origin, and the physical meaning of applying boundary conditions at $\xi = 0$ is unclear.

In order to overcome this problem, we use the following method. As explained in § 2.2, the entropy of any physical flow approaches a finite value as $r \rightarrow 0$, while the entropy of the self-similar solution diverges at this limit. Thus, instead of directly analyzing the global stability of the decelerating shock waves through an analysis of the Sedov-von Neumann-Taylor solutions, we analyze the stability of modified solutions which deviate from the Sedov-von Neumann-Taylor solutions in a region near the origin, $0 < \xi < \xi_0(t)$ with $\xi_0(t) \rightarrow 0$ as $R \rightarrow \infty$ (where, e.g., the entropy of the modified solution is finite). As we show below, the stability properties of the solutions are independent of the details of the solution at $0 < \xi < \xi_0(t)$, and are completely determined by the requirement that the perturbed solution remains self-similar at $\xi > \xi_0(t)$. The stability of the Sedov-von Neumann-Taylor solutions is obtained by examining the solutions in the limit $\xi_0 \rightarrow 0$. We show below that the derived growth rates converge to finite values in this limit.

Since the solution we consider deviates from the self-similar solution at $\xi < \xi_0(t)$, a discontinuity (of the entropy or of one of the derivatives of the velocity and pressure) occurs at $\xi_0(t)$. Such a contact or weak discontinuity propagates along a characteristic of the flow, i.e. $\xi_0(t)$ must be a characteristic. Since C_+ characteristics of the Sedov-von Neumann-Taylor solutions originating from any point $\xi < 1$ overtake the shock front $\xi = 1$ (Waxman & Shvarts 1993), $\xi_0(t)$ must coincide with a C_0 characteristic of the Sedov-von Neumann-Taylor solution. The equation describing the time evolution of C_0 characteristics is

$$\frac{d}{dt}(\xi_0 R) = \dot{R} \xi_0 U(\xi_0), \quad (21)$$

which may be written also as (Waxman & Shvarts 1993)

$$\frac{d \log \xi_0}{d \log R} = U(\xi_0) - 1. \quad (22)$$

For $\xi_0 \rightarrow 0$ Eq. (22) can be approximated using eq. (11) as

$$\frac{d \log \xi_0}{d \log R} = \frac{1}{\gamma} - 1 \Rightarrow \xi_0 \sim R^{1-1/\gamma} \sim t^{\alpha(1-1/\gamma)}. \quad (23)$$

Thus, at late times ξ_0 tends to zero, i.e. the fractional size of the non-self-similar region tends to zero.

The required additional boundary condition for the perturbed solution is obtained using the following argument. The unperturbed solution is described by the self-similar solution in a region $\xi_0(R) < \xi = r/R < 1$. $r_c(t) = \xi_0 R$ is the radius of a sphere across which there is no mass flux, and within which the solution deviates from the self-similar solution. In the perturbed solution, the surface across which there is no mass flux is deformed

and its radial distance from the origin depends on direction, $\tilde{r}_c(\theta, \phi, t)$. The evolution of this surface with time is given by

$$\frac{d\tilde{r}_c}{dt} = u_r(\tilde{r}_c, \theta, \phi, t) = \dot{R}\tilde{\xi}_0 U(\tilde{\xi}_0) + f\dot{R}\tilde{\xi}_0 \delta U_r(\tilde{\xi}_0) Y_{lm}(\theta, \varphi) + \tilde{\xi}_0 \delta R \frac{\partial}{\partial r}(\dot{R}\tilde{\xi}_0 U(\tilde{\xi}_0)), \quad (24)$$

where $\tilde{\xi}_0 \equiv \tilde{r}_c/(R + \delta R)$, u_r is the perturbed radial velocity (the transverse flow leads only to second order corrections to the evolution of $\tilde{r}_c$), and the last two terms on the right hand side are the Lagrangian variation in $u_0(\xi_0 R, t) = \dot{R}\xi_0 U(\xi_0)$. As for the unperturbed solution, we assume that a perturbed solution may be constructed, such that it deviates from self-similarity only within $r(\theta, \phi, t) < \tilde{r}_c(\theta, \phi, t)$. In order to obtain a global self-similar perturbed solution, defined over the same ξ range as the unperturbed solution, we require $\tilde{\xi}_0(\tilde{R})$ to coincide with $\xi_0(R)$, i.e. [see eq. (22)]

$$\frac{d \log \tilde{\xi}_0}{d \log \tilde{R}} = U(\tilde{\xi}_0) - 1, \quad (25)$$

or [see eq. (21)]

$$\frac{d\tilde{r}_c}{dt} = \frac{d}{dt}(\tilde{\xi}_0 \tilde{R}) = \frac{d(R + \delta R)}{dt} \tilde{\xi}_0 U(\tilde{\xi}_0). \quad (26)$$

Comparing equation (24) with equation (26), and using $\tilde{\xi}_0 = \xi_0$, we obtain

$$\delta U_r(\xi_0) = qU(\xi_0) - \xi_0 U'(\xi_0). \quad (27)$$

Eq. (27) provides the additional constraint required for determining q : Integration of equations (17) starting at the shock front using the shock boundary conditions (20) will lead to solutions satisfying the condition (27) only for some particular values of q .

The procedure described above determines $q(l, \gamma, \omega, \xi_0(t))$. The time dependence of ξ_0 implies a time dependence of q , while the derivation of eqs. (17) is valid under the assumption that q is time independent. The corrections to eqs. (17) due to the time dependence of q may be neglected if perturbations evolve much faster than the rate at which q changes, i.e. for $|t/s| \ll |s/\dot{s}|$ which may be written as

$$|q| \gg (1 - U(\xi_0)) \left| \frac{d \log(q)}{d \log(\xi_0)} \right|. \quad (28)$$

As we show in the following section, $s = q\alpha$ converges to a finite value in the limit $\xi_0 \rightarrow 0$. Thus, the value of s in this limit provides the growth rate of global perturbations to the self-similar solutions. Moreover, the value of s obtained for finite ξ_0 gives the growth rate for global perturbations to solutions which deviate from the self-similar solution at $\xi < \xi_0$, provided the condition given in eq. (28) is satisfied.

4. NUMERICAL RESULTS

We present in this section the results of numerical calculations of $s(\gamma, \omega, l, \xi_0)$. Eqs. (17) are integrated starting at the shock front, with boundary conditions (20), using standard error control Runge-Kutta integration scheme. The value of s is obtained, using Newton-Raphson iterations, by requiring the boundary condition (27) to hold. In addition to presenting results as

FIG. 1.— Perturbation growth rate, s , as function of wave number for various values of m_0 , the fraction of self-similar solution mass contained in the self-similar part of the flow [see eq. (29)], for $\omega = 0, \gamma = 1.5$. The lines denoted "R&V" show the results of the analysis of Ryu & Vishniac (1987). The perturbation amplitude evolves as $f \propto t^{\text{Re}(s)} \exp(i\text{Im}(s) \ln t)$.

FIG. 2.— Perturbation growth rate, s , as function of wave number for various values of m_0 , the fraction of self-similar solution mass contained in the self-similar part of the flow, for $\omega = 0, \gamma = 1.1$. The lines denoted "R&V" show the results of the analysis of Ryu & Vishniac (1987). The perturbation amplitude evolves as $f \propto t^{\text{Re}(s)} \exp(i\text{Im}(s) \ln t)$.

function of ξ_0 , we also present results as a function of $m_0(\xi_0)$, where m_0 is the fraction of self-similar solution mass enclosed within the self-similar region,

$$m_0 = \frac{\int_{\xi_0}^1 G(\xi) \xi^2 d\xi}{\int_0^1 G(\xi) \xi^2 d\xi}. \quad (29)$$

Some values of ξ_0 for different m_0 's and γ 's in the $\omega = 0$ case are shown in table 1.

The results for $\omega = 0$, i.e. the frequency spectra of the real and imaginary parts of s , are shown in figures 1 and 2 for $\gamma = 1.5$ and $\gamma = 1.1$ respectively. The spatial dependence of the perturbations to the self-similar profiles of flow variables are shown for these cases in figures 3 to 6. The convergence of s to finite values in the limit $m_0 \rightarrow 1$ justifies the use of the method described in the previous section (see last paragraph of § 3.2). The self-similar, asymptotic solutions are stable for large γ , and unstable for small γ . The various stability regions

FIG. 3.— The real and the imaginary parts of δG as function of $1 - m(\xi)$, where $m(\xi)$ is the fraction of self-similar solution mass in $[0, \xi]$ [see eq. (29)], for the $\omega = 0, \gamma = 1.5, l = 10$ case ((a)-(b)) and for the $\omega = 0, \gamma = 1.1, l = 40$ case ((c)-(d)). The physical solution oscillates between the real and the imaginary parts.

FIG. 4.— The real and the imaginary parts of δP as function of $1 - m(\xi)$, where $m(\xi)$ is the fraction of self-similar solution mass in $[0, \xi]$ [see eq. (29)], for the $\omega = 0, \gamma = 1.5, l = 10$ case ((a)-(b)) and for the $\omega = 0, \gamma = 1.1, l = 40$ case ((c)-(d)). The physical solution oscillates between the real and the imaginary parts.

FIG. 5.— The real and the imaginary parts of δU_r as function of $1 - m(\xi)$, where $m(\xi)$ is the fraction of self-similar solution mass in $[0, \xi]$ [see eq. (29)], for the $\omega = 0, \gamma = 1.5, l = 10$ case ((a)-(b)) and for the $\omega = 0, \gamma = 1.1, l = 40$ case ((c)-(d)). The physical solution oscillates between the real and the imaginary parts.

FIG. 6.— The real and the imaginary parts of δU_T as function of $1 - m(\xi)$, where $m(\xi)$ is the fraction of self-similar solution mass in $[0, \xi]$ [see eq. (29)], for the $\omega = 0, \gamma = 1.5, l = 10$ case ((a)-(b)) and for the $\omega = 0, \gamma = 1.1, l = 40$ case ((c)-(d)). The physical solution oscillates between the real and the imaginary parts.

in the $[\omega, \gamma]$ plane are shown in fig. 7. For all values of γ , the perturbation amplitude shows oscillatory behavior ($\text{Im}(s) \neq 0$) at all but the lowest ($l = 1$) wave numbers.

These oscillations are damped ($\text{Re}(s) < 0$) in the stable solutions, and amplified ($\text{Re}(s) > 0$) over a wide range of

FIG. 9.— The real part of the perturbation growth rate, s , as function of wave number for $\omega = 0, \gamma = 1.06$, compared with the values measured by Grun et al. (1991). The measured values are higher than the growth rates obtained for the asymptotic, $m_0 \rightarrow 1$, self-similar solutions. However, as explained in the discussion, the flow in the experiment reaches only $m_0 \lesssim 0.87$.

explained in appendix A.

The growth rates obtained by our method for finite ξ_0 , $s(l, \gamma, \omega; \xi_0)$, describe the growth rates of global perturbations for solutions that deviate from the self-similar solutions at $\xi < \xi_0$, provided the constraint of Eq. (28) is satisfied. Figure 8 shows the values of $m_0(\omega, \gamma)$, the fraction of self-similar solution mass contained in the self-similar part of the flow, $\xi_0 < \xi < 1$ [see eq. (29)], above which this condition is satisfied. For small γ values, e.g. $\gamma < 1.06$ for $\omega = 0$, our analysis provides accurate s values for arbitrarily small m_0 .

Based on the current analysis, one can not infer the existence of instability of the pre-asymptotic flow, i.e. for $m_0 < 1$, at $[\omega, \gamma]$ regions where the asymptotic, $m_0 \rightarrow 1$, solutions are stable (see figure 8). However, we find that the pre-asymptotic flow is in general less stable than the asymptotic flow. In the stable region of the $[\omega, \gamma]$ plane (figure 8), we find (see figure 1) slower decay rates of the perturbation amplitudes for $m_0 < 1$ ($\xi_0 > 0$), compared to the decay rates obtained for the asymptotic solutions, $m_0 \rightarrow 1$ ($\xi_0 \rightarrow 0$). In the unstable region, we find growth rates which are larger than those obtained for the unstable asymptotic solutions (see figure 2). This implies that as the shock wave evolves and approaches self-similarity, the perturbation growth rates are also evolving, and are determined at any given time by the appropriate value of m_0 . For unstable shock waves, the over all growth of

perturbations depends on the evolution of m_0 at early times.

In the experiment of Grun et al. (1991), the ambient gas adiabatic index was 1.06 ± 0.02 , and the maximum growth rate was $s \cong 1.6$ at $kR \cong 10$ (we will assume $kR \sim l$ though the wave numbers in the experiment were obtained from the projection onto a plane of the edge of an unstable sphere, thus kR is not identical to l). The numerical and the experimental results for $\omega = 0$ and $\gamma = 1.06$ are shown in figure (9) (Note, that our method is valid in this case for any m_0 , see figure 8). The maximal growth rate of perturbations to the asymptotic solution is $s \cong 1$ at $l \cong 60$. The growth rate is larger, however, for $m_0 \leq 0.7$. We can estimate m_0 in the experiment from figure 3(a) of Grun et al. (1991). The radius beyond which the shock expands according to the self-similar scaling is $R_{initial} \cong 7mm$, and the perturbations keep growing until $t \cong 200ns$, where the shock radius is $R_{final} \cong 14mm$. Thus, m_0 is given by $m_0(R) = 1 - (R_{initial}/R)^3$, and the maximum value of m_0 is $m_0 \approx 0.87$. This implies that the experiment does not measure the asymptotic ($m_0 \rightarrow 1$) value of s , but rather $s(m_0)$ with $m_0 < 0.87$. This may account for the large growth rates determined by the experiment.

The most unstable modes predicted by our linear analysis are still characterized by larger wave numbers, $l > 50$, than obtained by Grun et al. (1991). However, since the growth rates predicted by our analysis for large wave numbers are large, we expect the evolution of perturbations to become non-linear at an early stage. The non-linear interaction at large wave numbers may lead to perturbation amplitudes at smaller wave numbers, $l \sim 10$, which are larger than predicted by linear analysis. Our predictions may be tested in future experiments, by controlling m_0 . For example, lower gas densities or higher ablated material densities will make m_0 smaller, leading to higher perturbation growth rates.

Finally, we note that for stable asymptotic shocks, e.g. the $[\omega = 0, \gamma = 5/3]$ case relevant for the "Sedov-phase" of supernovae shocks, our analysis results do not differ significantly from those of Ryu & Vishniac. However, since in general we find that the flow is less stable at small m_0 , it is possible that instabilities do arise during the pre-asymptotic stage of shock evolution. This should be checked by numerical simulations.

DK thanks Re'em Sari for discussions that triggered his interest in this problem. This research was partially supported by AEC and MINERVA grants.

APPENDIX

A. THE ASYMPTOTIC BEHAVIOR FOR LARGE M_0 VALUES

As indicated in § 4, our solution for the growth rate s tends to the Ryu & Vishniac solution as m_0 tends to 1, for sufficiently large l , $l > l_0$. We explain here the reason for this convergence, and the reason for the deviation of our results from those of Ryu & Vishniac for $l < l_0$. Moreover, we will prove that any finite inner boundary condition will yield the correct solution for sufficiently large l .

The perturbation eqs. (17) can be simplified in the limit $\xi \rightarrow 0$ by using (following Ryu & Vishniac (1987)) the asymptotic behavior, Eq. (11), of the self-similar solution in this limit. Assuming that in this limit the perturbations behave as

$$\delta P = \delta P_0 \xi^d, \quad \delta U_r = \delta U_{r0} \xi^{d-a}, \quad \delta U_T = \delta U_{T0} \xi^{d-a}, \quad \delta G = \delta G_0 \xi^{d-2}, \quad (A1)$$

a set of four linear equations is obtained for $\delta P_0, \delta U_{r0}, \delta U_{T0}$, and δG_0 . In order for a nontrivial solution to exist, the

determinant of the coefficient matrix of these equations must vanish,

$$\begin{vmatrix} A_{11} & A_{12} & A_{13} & 0 \\ A_{21} & A_{22} & 0 & A_{24} \\ 0 & 0 & A_{33} & A_{34} \\ A_{41} & A_{42} & 0 & 0 \end{vmatrix} = 0, \quad (\text{A2})$$

where

$$\begin{aligned} A_{11} &= q - \omega + 3/\gamma + (d - 2)(1/\gamma - 1), \\ A_{12} &= (d + 1), \\ A_{13} &= -l(l + 1), \\ A_{21} &= -aP_1/G_0, \\ A_{22} &= \delta + q + 2/\gamma - 1 + (1/\gamma - 1)(d - a), \\ A_{24} &= d, \\ A_{33} &= \delta + q + 2/\gamma - 1 + (1/\gamma - 1)(d - a), \\ A_{34} &= 1, \\ A_{41} &= -\gamma q + (\gamma - 1)(d - a), \\ A_{42} &= -\gamma(a - 2). \end{aligned} \quad (\text{A3})$$

Eq. A2 is therefore a fourth order polynomial equation for d . If four different solutions d exist, none of the powers in Eq. A1 is zero, then any solution of the perturbation equations is given, near the origin, by a linear combination of the power-law solutions corresponding to different values of d . For $l > l_0$, four different solutions to the polynomial eq. for d exist, with only one negative $d - a$ value (the smallest power in Eq. A1). Requiring the pressure to be finite at the origin is equivalent in this case to requiring that the solution be a combination of the 3 approximate solutions corresponding to positive $d - a$ values. This uniquely determines the value of q . Thus, the method used by Ryu & Vishniac, seeking solutions that do not diverge near the origin by requiring finite boundary condition, yields the correct value of q for $l > l_0$.

In the region $l < l_0$, more than one solution with negative $d - a$ exists. In this case, requiring the solution not to diverge at the origin does not yield the correct solution. It is for this reason that the numerical method used by Ryu & Vishniac does not converge to the correct solution of q for $l < l_0$. In contrast, our numerical method is free of such difficulties. Note, that in the limit $l \rightarrow 0$, one of the solutions to Eq. A2 is $d = 0$, which implies the existence of an additional solution, not of the form given by Eq. A1. This additional solution is given analytically in appendix § B.

B. THE BEHAVIOR FOR SMALL WAVE NUMBERS

In the self-similar solution, any flow variable $w(r, t)$ (where w may stand, e.g., for ρ, u, c) is given in the form $w(r, t) = R^{e_1} \dot{R}^{e_2} W(\xi)$ where $\xi = r/R$. For the problem under consideration, R is given in the form $R = A(t - t_0)^\alpha$. The parameters e_1 and e_2 and the function W depend only on the parameters γ and ω (which determine also the value of α). Thus, for given γ, ω the solution depends on only two parameters, A and t_0 .

An approximation to the perturbed solution in the limit of small wave numbers, $l \rightarrow 0$, may be obtained using the following argument (Gurevich & Rumyantsev 1970). For small wave numbers, large wave lengths, we may assume that the flow along any direction θ, ϕ evolves with time as if it were part of a spherically symmetric solution. This approximation is valid as long as the time scale for the evolution of the perturbation is shorter than the time it takes sound waves to propagate tangentially over a distance $\sim R/l$ over which the deviation from isotropy is appreciable. This approximation gives, of course, the exact solution for $l = 0$, and may be expected to provide an approximate description of the behavior at $l \rightarrow 0$. Since the spherically symmetric solution depends on only two parameters, A and t_0 , the perturbed solution is given in this approximation in the form

$$w(r, \theta, \varphi) = R_p^{e_1} \dot{R}_p^{e_2} W(r/R_p), \quad (\text{B1})$$

where

$$R_p = R(t; A(\theta, \varphi), t_0(\theta, \varphi)). \quad (\text{B2})$$

Here, it is assumed that $A(\theta, \varphi)$ and $t_0(\theta, \varphi)$ differ from their values in the spherical solution, A_s and t_{0s} , only infinitesimally, and that they are slowly varying functions of (θ, φ) .

Using spherical harmonics decomposition,

$$\begin{aligned} A(\theta, \varphi) &= A + \delta A Y_{lm}(\theta, \varphi), \\ t_0(\theta, \varphi) &= t_0 + \delta t_0 Y_{lm}(\theta, \varphi), \end{aligned} \quad (\text{B3})$$

one obtains

$$\begin{aligned} \delta R(t, \theta, \varphi) &= \left[\frac{\partial R}{\partial A} \delta A + \frac{\partial R}{\partial t_0} \delta t_0 \right] Y_{lm}(\theta, \varphi), \\ \delta w(r, \theta, \varphi) &= R^{e_1} \dot{R}^{e_2} \left[e_1 - \xi W' + e_2 \frac{R \delta \dot{R}}{\dot{R} \delta R} \right] \delta R \end{aligned} \quad (\text{B4})$$

for the deviation from the spherical solution.

From equation (B4) it is clear that there are two perturbation modes: one is associated with changes in t_0 , and the other with changes in A . Since for $R(t) = A(t - t_0)^\alpha$ we have $\delta R(t) = R(\delta A/A + \delta t_0/(t - t_0))$, $s = 0$ is obtained for perturbations associated with changes in A , and $s = -1$ is obtained for perturbations associated with changes in t_0 .

The radial dependence of the perturbations is given by

$$\begin{aligned}\delta G(\xi) &= [-\omega - \xi G'(\xi)/G(\xi)]G(\xi), \\ \delta U_r(\xi) &= [\delta - 1 - \xi U'(\xi)/U(\xi)]U(\xi), \\ \delta P(\xi) &= [-\omega + 2\delta - \xi P'(\xi)/P(\xi)]P(\xi)\end{aligned}\tag{B5}$$

for t_0 associated perturbations, and by

$$\begin{aligned}\delta G(\xi) &= [-\omega - \xi G'(\xi)/G(\xi)]G(\xi), \\ \delta U_r(\xi) &= [-\xi U'(\xi)/U(\xi)]U(\xi), \\ \delta P(\xi) &= [2 - \omega - \xi P'(\xi)/P(\xi)]P(\xi)\end{aligned}\tag{B6}$$

for A associated perturbations.

The tangential velocity perturbation may be obtained by integrating the third equation of (17). Since it is proportional to $\nabla_{\mathbf{T}} Y_{lm}(\theta, \varphi)$, the tangential velocity perturbation tends to zero as l tends to zero. It is straight forward to show that for every ω and γ equation (B5) is a solution of equations (17) with $l = 0$ and $s = -1$, and that equation (B6) is a solution of equations (17) with $l = 0$ and $s = 0$. This can be most easily inferred from equation (7), equation (9), and energy conservation,

$$C^2 = \frac{\gamma(\gamma - 1)}{2} \frac{U^2(1 - U)}{\gamma U - 1}.\tag{B7}$$
